Abstract

Obese patients are known to have greater risks to develop hypertension, coronary vascular disease, and insulin resistance, and more attention has been recently paid to the impact of obesity on kidney. This study was conducted to investigate whether obese children have higher risk of renal injury as well as adults. Eighteen hundred and thirty school children aged 6-14 years with abnormal urinary findings on thrice occasions detected by the screening program for renal disease in Japan were enrolled. Of them, 27 children with nephritis or suspected nephritis diagnosed by persistent proteinuria with hematuria were compared to 588 without urinary abnormalities regarding their body mass index (BMI), blood pressure (BP), and serum level of total cholesterol. BMI and systolic BP (mmHg) were significantly higher in the former than in the latter. As a result, obesity may be associated with the development of renal injury even in childhood.

Materials and Methods

In Japan, the annual urinary screening for renal disease of elementary and junior high school students has been mandatory since 1974 when the Ministry of Education revised the school health law to identify children at risk of renal failure in adulthood. According to this law, detailed urinalysis is performed for all elementary and junior high-school students living in Japan. The program is described in detail previously.6 Briefly, patients positive for protein and/or occult blood on two serial occasions are subjected to a 3rd examination: these patients are asked to attend a medical center for a detailed examination consisting of urinalysis, medical history, physical examination including measurements of weight and height, and laboratory studies, performed by pediatricians. This approach aims to detect any clinical, hematological, or serological abnormalities associated with renal disease. After the 3rd examination, presumptive diagnoses are made and grouped into 6 categories as shown in the Table 1.

As a result, eighteen hundred and thirty school children aged 6-14 years with abnormal urinary findings detected by the screening program in part of Tokyo in 2007 were enrolled in this study. For comparison of the nutritional status among the categorized subjects, body mass index (BMI) was applied.

For statistical analysis, analysis of variance (ANOVA) and Dunnett’s test were used among the 6 groups. P value less than 0.05 was considered significant. All numerical data were expressed as mean and standard deviation.

Results

Eighteen hundred and thirty subjects were classified into 6 categories (Table 1): 588 in A, 112 in B, 278 in C, 570 in D, 255 in E and 27 in F. As shown in the Table 2, the BMI was significantly higher only in F (nephritis/suspected nephritis) than in groups A (no kidney disease: P=0.039).

We further analyzed the difference in blood pressure and serum levels of total cholesterol between the category A and category F because obesity is known to influence these parameters: P=0.039). As a result, eighteen hundred and thirty school children aged 6-14 years with abnormal urinary findings detected by the screening program in part of Tokyo in 2007 were enrolled in this study. For comparison of the nutritional status among the categorized subjects, body mass index (BMI) was applied.

Discussion

It is estimated that 7% of children in the world are obese.7 The national surveys from the USA found that since 1980 the number of overweight children has doubled, and the number of overweight adolescents has tripled.8 As several lines of evidence demonstrated that ORG should be identified as an isolated complication of obesity in adults, attention has been recently paid to the impact of obesity not only on hypertension, coronary vascular disease, and insulin resistance but also on kidney.1 In fact, obese subjects, even in the absence of diabetes, can have glomerulomegaly, thickening of glomerular basement membranes, proliferation of mesangial matrix, focal segmental glomerulosclerosis (FSGS) and increased microlumuninuria called ORG, both in normotensive and hypertensive subjects.3 Kambham et al. brought to our attention a tenfold increase in the prevalence of ORG,1 from 0.2% in 1986-1990 to 2% in 1996-2000 in obese subjects (BMI >30 kg/m²).

These findings prompted us to investigate whether overweight children have an independent risk of developing to kidney disease as well as in adult. As a result, we firstly demonstrated that children having both proteinuria and hematuria are more obese than those without urine abnormalities. This suggests that ORG may develop even in childhood.

In addition to BMI, there was a significant difference only in systolic blood pressure between group A and group F, while there were no significant differences among group A, B, C, D, and group E as shown in the Table 2. Recent observations revealed that systolic blood pressure correlates well with BMI than diastolic blood pressure. Furthermore, a meta-analysis indicated that the change in blood pressure associated with body weight is more pronounced in systolic blood pressure than in diastolic blood pressure.10
lead to the finding that there was only significant difference in systolic blood pressure but not in diastolic blood pressure.

The pathogenic mechanism responsible for proteinuria in obese subjects is speculated to be from glomerular hyperfiltration based on direct observation of increased glomerular filtration rate in obese individuals, and indirectly from similarity in clinical course between ORG and renal diseases characterized by glomerular hyperfiltration, such as secondary FSGS.11,12 In addition, recent study revealed that adipose tissue plays a pivotal role in the development of renal injury. Adipose tissue is recognized as a source of inflammatory cytokines such as tumor necrosis factor-α (TNFα), interleukin-6 (IL-6) and C-reactive protein (CRP).13 CRP is higher in men and women with an elevated body mass index.14

Thus, obesity is associated with a state of low-grade systemic inflammation, which may contribute to renal injury and cardiovascular disease. In fact, recent observation confirmed this finding demonstrating the increased gene expression of inflammatory cytokines, such as TNFα or IL-6.16

BMI, body mass index; *P<0.05 compared to Group A (children with no kidney diseases: controls).

Table 1. Criteria of diagnoses in the urinary screening program in Japan.

In conclusion, although the further study is clearly needed, obesity can be associated with the development of renal injury characterized by proteinuria and hematuria even in childhood and early intervention to lose weight should be mandatory, as the benefit of weight loss in ORG in adult is reported to be limited.
