Abstract

In the cave of Les Fraux (Dordogne, France) numerous traces of fires are visible in the galleries. A multidisciplinary investigation was carried out to study these fires. This paper presents the methodology applied for the hearth study. It is based on the examination of the thermoluminescence (TL) of quartz and the magnetic susceptibility of iron oxides. First of all, magnetic susceptibility was measured on the surface of hearths. Based on both susceptibility mapping and visible sediment characteristics, small sediment samples (1-2 g) were taken. Subsequently, quartz grains were extracted from the sediment samples. Fourteen thermal references were obtained by heating (from 200 to 650°C) fractions of the pristine unfired cave sediment. Comparing the TL signal of anciently heated quartz to the reference samples allowed to obtain the maximum equivalent temperature attained for each sample extracted from ancient fires. Consequently, the correspondence between magnetic susceptibility and temperature allowed for the reconstruction of a paleotemperature map of the study area. This research provides information about fire intensity in the cave, which can help to understand its function.

Introduction

Accidentally discovered in 1989, the cave of Les Fraux is located at Saint-Martin-de-

Fressengeas, Dordogne, France (coordinates: x=484.030 y=2050.670 z=240 m) (Carozza *et al.*, 2009). This cave is a rare example of a Bronze Age site, with both archaeological remains (ceramics and hearths) and rock art (incision, engraving, fingerings) preserved. The preservation of this site is exceptional as the cave entrance collapsed right after its last human occupation, 3300 years ago. Multiple traces of fire (reddened areas, ashes, charcoal) are visible in the cave galleries.

This study was carried out to contribute to the characterisation of the human occupation of the cave, and particularly the fire impact on the natural site (sediment and rock walls) was focused on. The intensity and the function of hearths were investigated from a multidisciplinary point of view. The objective of this article is to introduce a novel method for the thermal characterisation of hearths. For these purposes, thermoluminescence (TL) and magnetic susceptibility measurements were carried out to characterise the heating of the sediment forming the ground of the ancient fires.

Materials and Methods

Thermoluminescence

Thermoluminescence is usually used to date heated materials for chronological purposes (McKeever and Chen, 1997). In this study we extracted part of the usual TL dating protocol in Bordeaux and determined the paleotemperature of samples using the variation of the TL signal with differing ancient heating conditions (temperature and duration) (Lahaye *et al.*, 2006; Roque *et al.*, 2004; Valladas, 1981; Vieilleveigne *et al.*, 2007).

Thermoluminescence measurements were carried out with an automatic equipment that was designed and built in the Bordeaux laboratory. The main parts of this apparatus are a beta ⁹⁰Sr source used to simulate the natural irradiation, a heating chamber surmounted by optical filters, a PM tube (EMI 9813 QA) and associated electronics that record the luminescence signals as a function of temperature. The TL signals of the quartz grains extracted from sediments are recorded while heating from room temperature to 500°C at 4°C/s under a neutral nitrogen atmosphere. The optical window selected ranged from 350 to 475 nm, in accordance with the main luminescence spectrum of quartz. A chamber furnace (Eurotherm 2416CG, CARBOLITE) was used to prepare the thermal references by heating the pristine sedimentary material sampled in the cave according to a precisely designed heating cycle detailed further on.

Magnetic susceptibility

Magnetic susceptibility is indicative of the magnetisation potential of a material when a magnetic field is applied. Magnetic susceptibility measurements can be done *in situ* and quickly give indications on the magnetic mineral content. Numerous minerals contain iron (Cornell and Schwertmann, 2003) and contribute to the magnetic susceptibility. In descending order of magnetic susceptibility, there are magnetite, maghemite, hematite, goethite, lepidocrocite, etc.

Heating by fire generates mineralogical transformations, particularly among iron oxides. Transformation and destruction depend on the temperature attained. For example, by thermal dehydration lepidocrocite can transform into magnetite (Cudennec and Lecerf, 2005) implying an enhanced magnetic susceptibility.

Heated sediment contains more magnetic minerals, hence has higher values of magnetic susceptibility than unheated sediment:

the higher the attained temperatures, the stronger the magnetic susceptibility.

Measurements of magnetic susceptibility *in situ* were done with a contact susceptometer: KT-9, Exploranium.

Results and Discussion

Methodological overview

On the site first, a map of magnetic susceptibility of the hearth was reconstructed by surface measurements in the fire area selected. This set of measurements allowed choosing the sampling locations more precisely in a subsequent step. A sample of unheated sediment was also taken out to create a thermal reference.

Then, in laboratory, the quartz grains were extracted from the sediment samples and the TL signal was measured. The comparison of the TL signal between hearth samples and the thermal references allows determining the paleotemperature of each sample. Finally, combining the on-site magnetic susceptibility measurements and paleotemperature, we obtained a paleotemperature map of the entire hearth.

Magnetic susceptibility mapping

This study focused on the peculiar hearth presented in Figure 1. Firstly, a map of magnetic susceptibility (Figure 2) was constructed using a KT-9 susceptometer on a limited zone around the shaped hearth of the cave. The map shows three zones of high magnetic susceptibility corresponding to the most concentrated magnetic phases, which we can assume to be the most heated places.

Sampling and quartz extraction

Based on this, small samples (1-2 g) were extracted from the hearth (white crosses show samples locations, Figure 1). An additional sample of unheated sediment of the cave (same geological origin) was selected to obtain a thermal reference to be compared with samples of hearth sediment.

For TL measurements, quartz grains were extracted. After disaggregation of the sediment and sieving, grains sized between 200 and 500 μm were chemically treated. Carbonate phases were removed using HCl (1 M) and organic matter by washing with hydrogen peroxide. An additional treatment by immersion in concentrated HF solution (0.5 M) for one hour at room temperature was also performed to dissolve remaining clay materials and other minerals, such as feldspars. The aim of these chemical treatments is to obtain a sample solely consisting of quartz.

Thermoluminescence signal of thermal references and samples of hearth

Fourteen thermal references were processed in an electric oven according to a rigorously designed thermal protocol: a heating rate of 20°C/min from room temperature to the maximum temperature programmed, then one hour at this temperature and subsequently a cooling rate of 5°C/min. The maximum temperature was varied from 200 to 650°C, while keeping an unheated sample to compare with. These thermal parameters were chosen to correspond to heating rates and maximal temperatures in a real fire (Carrancho and Villalain, 2008; Werts and Jarhen, 2007).

To compare the TL signal between the reference and hearth samples, it is necessary to simulate on references the irradiation received by hearth samples during the time elapsed since the archaeological fire. Therefore a β irradiation and a preheating at 230°C were applied on reference materials. The evolution of the TL signal of the thermal reference samples as a function of the maximum temperature is shown on Figure 3. To illustrate the procedure, Figure 4 displays the natural TL signal of two different samples in association with their best-fit reference curves.

Determination of paleotemperature

To estimate the sample paleotemperature the TL signal of reference samples and those of hearth samples were compared based on the shape of the respective TL curves. Initially, a visual comparison was made, followed by studying the relative variance of the ratio of intensity between the natural signal of the sample examined with the regenerated signal of the reference samples. Finally, a hierarchic classification of all sample's curves (using STATISTICA, Ward method) was obtained based on the mutual comparison of the TL curves. Four groups are identified: i) unheated reference samples and one sample heated at 200°C; ii) reference samples heated at 250°C; iii) reference samples heated from 300°C to 450°C; and iv) reference samples heated from 500 to 650°C. Two examples of a TL signal and the comparison with reference samples are presented in Figure 4. The hierarchic classification confirms the visual interpretation of the curves, while sample number 1 seems unheated and number 9 appears to be heated at 375°C.

Figure 5. Paleotemperature map of the study area.

Table 1 summarises the paleotemperature results of each sample.

Combination of thermoluminescence and magnetic susceptibility

Combining the paleotemperatures found by TL with the values of magnetic susceptibility allows us to estimate the magnetic susceptibility as a function of paleotemperature, and therefore reconstruct a paleotemperature map of the study area (Figure 5). The three heated places are clearly visible, but additional temperature information obtained from this analysis is depicted.

Conclusions

The integration of TL and magnetic susceptibility measurements on burnt sediments permits us to map the paleotemperature attained by sediments over larger areas. This work presents a novel methodology to quantitatively study ancient fires. The temperature reached by the topmost sediment is a first indication of the intensity of ancient fires. To

Table 1. Summary of the paleotemperature results of each sample.

Sample no.	Temperature (°C)	Sample no.	Temperature (°C)
1	25	16	250
2	350	17	250

widen the scope of this study, experimental fires will be set up under environmental conditions material close to those encountered in the cave of Les Fraux. These experiments will enable validation of the results of this study's temperature determination and will enable modelling fires by their intensity, issued energy (light and heat) and quantity of wood consumed in a given duration.
